#### 1. BACKGROUND

The Reykjanes Ridge is one of the best examples of a hotspot-dominated mid-ocean ridge, and as such has been chosen by BRIDGE as the setting for one of its four regional projects. It has a number of unusual characteristics that are thought to be related to the proximity of the Iceland hotspot and mantle plume (e.g. Vogt, 1971; Courtney & White, 1986; Watson & McKenzie, 1991).

This cruise was funded by BRIDGE from a proposal on which R. C. Searle, B. E. Parsons and R.S. White were co-PIs.

#### 1.1 Gross morphology

The ridge extends along an azimuth of 216° from the Reykjanes Peninsular of southwest Iceland to the Bight Fracture Zone at 57°N, a distance of 900 km, and is spreading at a half-rate of about 12 mm a<sup>-1</sup> along 090° (Talwani et al., 1971; DeMets et al., 1989). The axial depth increases gradually from the 500 m at the insular margin to about 2000 m at the Bight Fracture Zone. Along the whole of its 900 km length the ridge has no transform faults or large non-transform offsets, and is thus spreading 36° obliquely. The onset of this phase of oblique spreading was slightly diachronous, beginning in the lower Miocene in the north and the middle to upper Miocene in the south (Vogt & Avery, 1974). Prior to that the ridge had many small-offset transform faults that are well-displayed in the magnetic (Vogt & Avery, 1974) and gravity fields (Haxby, 1987; Strange, 1991).

In the north the Ridge is morphologically more akin to a fast- than a slow-spreading ridge, having an elevated axial region rather than a median valley (Talwani et al., 1971). It also has low amplitude axis-parallel fault scarps, producing a regionally smoother seafloor than is found elsewhere in the north Atlantic (Searle & Laughton, 1981). This may be because the presence of anomalously hot mantle and high quantities of partial melt associated with the plume provide a thermal structure akin to that of a fast spreading ridge (Searle & Laughton, 1981; Brozena & White, 1990). The axial high gives way to a shallow median valley south of about 59.5°N.

High mantle temperatures associated with the Iceland plume appear to extend beyond Iceland and give rise to thickened oceanic crust near the Reykjanes Ridge, at least north of 59°N (see below). This partly explains the unusual elevation of the Ridge, although Strange (1991) has shown, using geoid and depth variations to estimate crustal thickness and temperature variations along the ridge, that the inferred crustal thicknesses are smaller than would be predicted for the inferred temperatures using the melting relationships of McKenzie and Bickle (1988).

Vogt & Johnson (1975) demonstrated the existence of SW-pointing V-shaped pairs of ridges with narrow apices. They are associated with strong gravity anomalies and are clearly a major feature of the Ridge. Vogt & Johnson suggested that these ridges represent the trails of volumes of excess melt migrating along the ridge away from the plume (Vogt, 1971). However, White (1992a) has questioned the possibility of such

axial flow. Searle & Laughton (1981) found no disruption of the seafloor tectonic fabric or other morphological feature associated with these ridges, and the origin of the ridges is still uncertain.

1.2 Crustal thickness and density

Seismic studies of deep crustal structure near the ridge axis have been concentrated between 59°N and 63°N. Near 60°N, Bunch & Kennett (1980) ran three axis-parallel lines between the axis and 9 Ma crust. Around 62°N there have been a number of studies. Talwani et al. (1971) made a number of refraction lines using sonobuoys, but did not reach mantle. Snoek & Goldflam (1978) interpreted a line about 2 Ma (20 km) northeast of the axis at 63°N, while Angenheister et al. (1980), Goldflam et al. (1980) and Ritzert & Jacoby (1985) reported on the southernmost axis-parallel RRSIP line over 12-15 Ma-old crust on the southeast flank of the ridge. These studies show 10-km-thick oceanic crust (about 3 km thicker than normal oceanic crust, though still less thick than under Iceland), and some anomalous transitional and mantle structure under the active spreading centre. Crustal thickness measurements from elsewhere in the northern Atlantic also show increased crustal thickness of 9-10 km due to the presence of the Iceland plume (White, 1992b; White et al., 1992).

Recently, White (1992c) has conducted wide-angle and normal-incidence multichannel seismic experiments on zero-age and 3 Ma lithosphere at 62°N (cruise CD70). Dr. M. Sinha (Cambridge) and Dr. C. Peirce (Durham) shot a further set of wide-angle seismic profiles along and across the ridge axis at 58°N in October 1993 (cruise CD81).

Owens et al. (1991) and Searle et al. (1992, 1994) data suggest the existence of a 10 km, second-order (non-transform) ridge offset at 58°N from bathymetry information and the inversion of the gravity and magnetics data from cruise EW9008, indicating thinning of the crust and magnetic layer and probably cooling of the mantle. This is the only ridge offset (apart from the ubiquitous en-echelon overlaps of AVRs) so far recognised along the Reykjanes Ridge.

Along the axis away from the 58°N offset, the residual Bouguer anomaly gets rapidly more negative, suggesting the existence of the same kind of crust/mantle segmentation as has been found in gravity and topography elsewhere along the Mid-Atlantic Ridge (Kuo & Forsyth, 1988; Lin et al., 1990). However, Bell & Buck (1992), analysing a single along-axis and widely-spaced cross-axis gravity profiles from Talwani et al. (1971) north of 60°N, suggest that the amplitude and wavelength of such segmentation are less than on other parts of the MAR, and interpret this to indicate that raised temperatures allow both a lower degree of segmentation in mantle upwelling (Parmentier & Phipps Morgan, 1990) and ductile flow in the lower crust to compensate partially for the initial crustal thickness variations induced by such segmentation.

1.3 Fine morphology

Following the early geophysical studies by Talwani et al. (1971), a relatively detailed study of the morphology of the Reykjanes Ridge crest between 58°N and 61°N was carried out by Searle & Laughton (1981) using GLORIA and other sonar. They found that the axial region of the Ridge is characterised by a succession of en echelon axial volcanic ridges (AVRs). The GLORIA survey showed that, as elsewhere on the midocean ridge, major normal faults are formed a few kilometres off-axis. These faults are, unusually, approximately parallel to the ridge axis and oblique to the spreading direction. The horizontal fault pattern appeared to be constant across the axial-high/median-valley boundary, but fault throws changed gradually across it. Similar AVRs and oblique normal faults were mapped at 62°N by Jacoby (1980) using a narrow-beam echosounder.

Hydrosweep multibeam and SeaMARC II bathymetry work (cruises EW9004 and EW9008) confirmed that en echelon AVRs are ubiquitous along the ridge axis, although their size and 'robustness' vary, not monotonically, along it (Appelgate and Shor, 1994; Parson et al., 1993). Parson et al. (1993) and Murton and Parson (1993) have analysed an 'axial profile' based on these data, and suggest that a number of scales of topographic segmentation can be recognised, which they attempt to relate to mantle melting and crustal magmatic processes. In particular they show that the area around 60°N sits on a 'knee' in the axial profile, whose gradient steepens substantially south of there. Moreover, there is at 60°N a robust axial high that comprises many well-developed AVRs. The reason for this local development is not yet known.

TOBI high resolution sidescan data gathered on cruise EW9008 show the AVRs to be of recent volcanic constructional origin, being composed of numerous small, point-source volcanoes, often aligned along what are taken to be buried fissures striking normal to the spreading direction. The AVRs show variable overall levels of acoustic backscattering and are affected by varying degrees of tectonism. These observations suggest variations in age, and have allowed an evolutionary sequence to be suggested (Parson et al., 1993; Murton and Parson, 1993).

#### 1.4 Geochemistry

Schilling et al. (1983) have summarised geochemical results from a detailed sampling programme along the ridge, which allow the influence of the Icelandic plume to be followed in detail. The cut-off for a plume-related geochemical signal appears to be just south of 60°N. Murton et al. (1993) increased Schilling et al.'s sampling density by a factor of ten, with sample stations 2 km or less apart.

#### 1.5 Hydrothermal activity

At present the only known vent field (Steinahóll) on the Reykjanes Ridge is in very shallow water on the Icelandic shelf near 63.1°N (Olafsson et al., 1991). Russian submersible dives took place near 58°25′N and reported hydrothermal staining (Kuznetsov et al. 1985). The US Navy's nuclear submersible NR1 dived near 61.8°N (Uchupi et al, unpublished data), and it is anecdotally reported that Bruce Heezen observed hydrothermal vents during that dive. However, no confirmation or documentary evidence of this can be found. German et al. (1993) sampled every 5 nautical miles along the Reykjanes Ridge, but found no vent sites in addition to Steinahóll.

# 2. OBJECTIVES

[The following is an extract from the ship-time proposal:]

1. Completion of a detailed multibeam bathymetry, gravity and magnetic survey of the Reykjanes Ridge, as a basis for further BRIDGE activities

If properly integrated with existing surveys, it will be possible to complete a near 100% bathymetric coverage together with closely-spaced magnetic and gravity profiles, extending at least 30 km off-axis on either side, over almost the whole ridge length. This off-axis coverage is sufficient to span the whole width of the AVR zone and will include magnetic anomaly 2 (2 Ma). We will publish the results in map form to assist in future work.

2. Production of bathymetric, gravity and magnetic databases for use in further BRIDGE activities

Our results will be combined with other existing data, particularly those from the 1990 Ewing cruises, and Seasat, Geosat and ERS-1 gravity to produce comprehensive digital databases of the area. Appropriate corrections will be applied to minimise navigation and cross-over errors. These digital databases will be made available to the BRIDGE community for the planning and interpretation of future work.

3. Completion of a sufficiently large and dense bathymetric, gravity and magnetic survey near 62°N to facilitate comprehensive analysis of the CD70 multichannel seismic experiment

We shall extend our coverage over a 100-km-long section near 62°N to 60 km off-axis to the SE, in order to include the whole area of the CD70 seismic survey. The aim is to enable modelling of the acoustic reverberations from seafloor topography, to use gravity to assist in modelling of crustal structure along the seismic lines and, most importantly, to provide the data to compare reflections from within the crust with surface topographic structure.

4. Investigation of crustal thickness variations along the Reykjanes Ridge axis
Four major seismic refraction experiments have been completed along the Reykjanes
Ridge spreading axis, which will provide firm control on crustal thickness at 58°N,
60°N, 62°N and 64°N. All will have been modelled with modern synthetic seismogram
methods. We shall use the continuous gravity and bathymetry measurements from this
cruise to interpolate between these fixed tie points, which will allow us to construct a
map of crustal thickness variations along the ridge axis. On a large scale, this will
enable us to test convection models of the flow of abnormally hot mantle material
brought to the base of the lithosphere by mantle plumes (e.g. Courtney & White, 1986;
Watson & McKenzie, 1991) and will provide constraints on melt productivity from the
Iceland plume (e.g. White, 1992a). On a smaller scale, it will allow us to map crustal
thickness variations on a segment scale to test theories of melt distribution with lateral
position at a crustal level.

# 5. Determination of complete pattern of segmentation and variability of magma supply along the Reykjanes Ridge

Ridge segmentation is now well-recognised on the Mid-Atlantic Ridge and East-Pacific Rise, and is recognised in topography, tectonic and volcanic patterns, and crustal thickness variations. Most of these can and have been related to variations in magma supply. There are many theoretical reasons why one would expect variability in melt migration (e.g. Scott and Stevenson, 1986), and it may well be that the segmentation observed at slow-and fast-spreading ridges reflects this variability. However, at the Reykjanes Ridge the expression of the variability may be different, and we will examine this. Topography, gravity and magnetics will be analysed to determine the current pattern of crustal segmentation along the ridge. We will determine the range of lengths of segments and their offsets, and compare these with data from other ridge areas and spreading rates. Particular attention will be paid to latitudinal variations and their comparison with geochemical anomalies, to try to determine the degree of influence of the plume. We will further test the possibility of a hierarchical segmentation pattern as proposed by Parson et al. (1993).

#### 6. Relationship of near-ridge variations to off-ridge features

Having determined the pattern of axial segmentation and other variations, we will trace these features off-axis where possible or, if there are no continuous off-axis traces, compare previous variation patterns along particular isochrons. We will attempt to compare any pattern found with that of the pre-Miocene transforms, although we realise that such a comparison really requires continuous high-resolution data connecting the two areas, and is properly the subject for a separate study. Spreading rate variations and ridge jumps or propagations will be determined along the whole ridge length. We will examine the relationship between topographic, gravity and magnetic evidence for segmentation, and here too examine the influence of the Iceland plume on these features.

# 7. Investigation of the structure and origin of the V-shaped ridge pairs

We aim to determine the crustal density/thickness and magnetisation, the degree and means of compensation, and the age/position of formation of the V-shaped ridges. We will also attempt to determine whether the patterns of volcanism and tectonism are different from those on the surrounding seafloor.

#### 8. The origin of axial valleys on normal slow-spreading ridges

Since the Reykjanes Ridge cross-section changes from axial high to median valley, we can use the observed variations in the gravity field along the Ridge to investigate this. We would, for example, investigate the effects of sub-surface loading by magma chambers, and the degree of isostatic or dynamic support of axial high or median valley. We will also investigate changes in faulting across the transition, which will reflect the brittle response to the underlying topographic forcing function.

# 3. WORK COMPLETED

The ship track is presented in figure 1. It was planned according to the above objectives and used satellite gravity data (Hwang et al., 1994) as a guide (figure 2). The satellite gravity was validated by the ship gravity and appeared to have good resolution down to 10-15 km wavelengths. We nominally divided the survey into five areas: D, E, F, G and H (following on from areas A, B and C of cruise EW9008 -Parson et al., 1993). These are indicated on figure 1 and are referred to in the sections below. Simrad EM12S-120 multibeam bathymetry, LaCoste-Romberg and Bell BGM3 gravity and total field magnetic data were recorded. Figure 3 displays the CD87 ship track together with other cruise tracks which collected similar data.

# 4. CRUISE NARRATIVE

#### (All times GMT)

Thur June 1	e 16 1994 (Julian Day 167)	
0910:	Departed Barry, set passage for Edoras Bank via Cork (for personnel transfer) and	

First science meeting with science party and RVS technicians. 1230:

#### Fri June 17 (168)

ku june 1/	(100)
0800:	Briefing meeting with Principal Scientist, Master, Chief Officer, Chief Engineer.
0000.	blicking meeting and processing

Switched on EM12S-120 for testing and practising operating and processing 0917:

Science briefing for crew. Making 11 knots on passage.

#### Sat June 18 (169)

1230:

0100:	Ship's clocks to GMT.
0600:	Wind freshening, force 6.
1500:	Full gale. Ship slowing.
1700:	EM12 records very poor - switched off.
*****	Mill a choting EM12 back on

Wind abating. EM12 back on. 2030:

#### Sun June 19 (170)

(170)
A/c for E-W run over Lorien Bank to calibrate EM12.
Hove to for velocity profile.
Began velocity dip no. 1, to 2000m.
Ended velocity dip.
Launched magnetometer. Begin slow turn to E to start EM12 pitch/roll calibration.
Commenced daily XBT deployments (see appendix A4).
End of EM12 calibration. S/c 306° for start of Edoras Bank line.

#### Mon June 20 (171)

Mon June 2	V(1/1)
0338;	A/c 323° at start of Edoras Bank line; running over Cambridge seismic line CAM77.
1200:	End of CAM77, A/c 285° for Reykjanes Ridge.

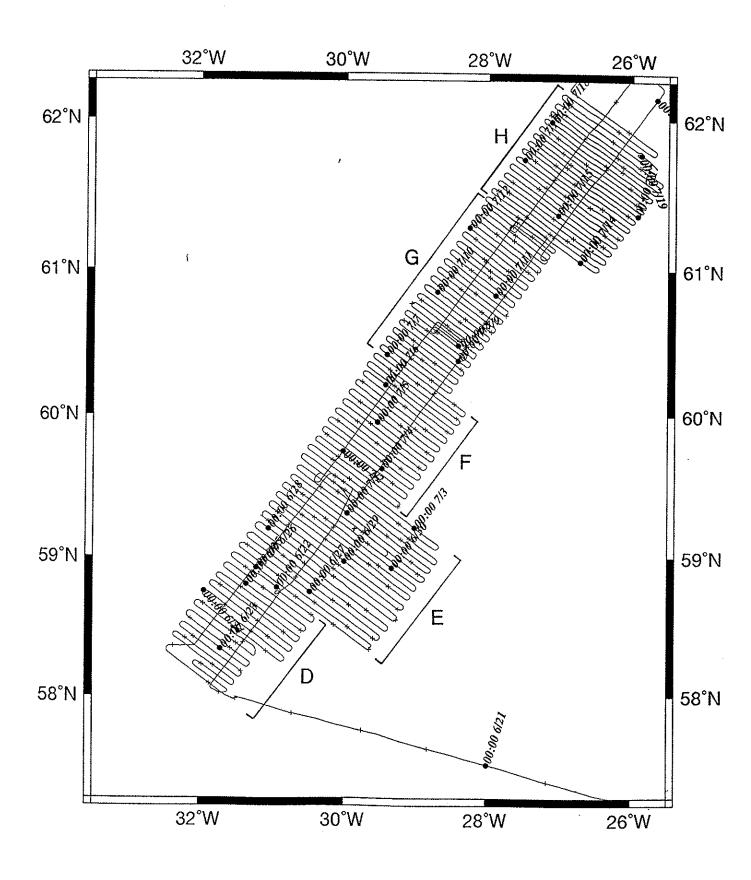

Figure 1 CD87 ship track. 0000Z is annotated every day, and the tickmarks are placed every 3 hours. The survey blocks are labelled D, E, F, G and H.

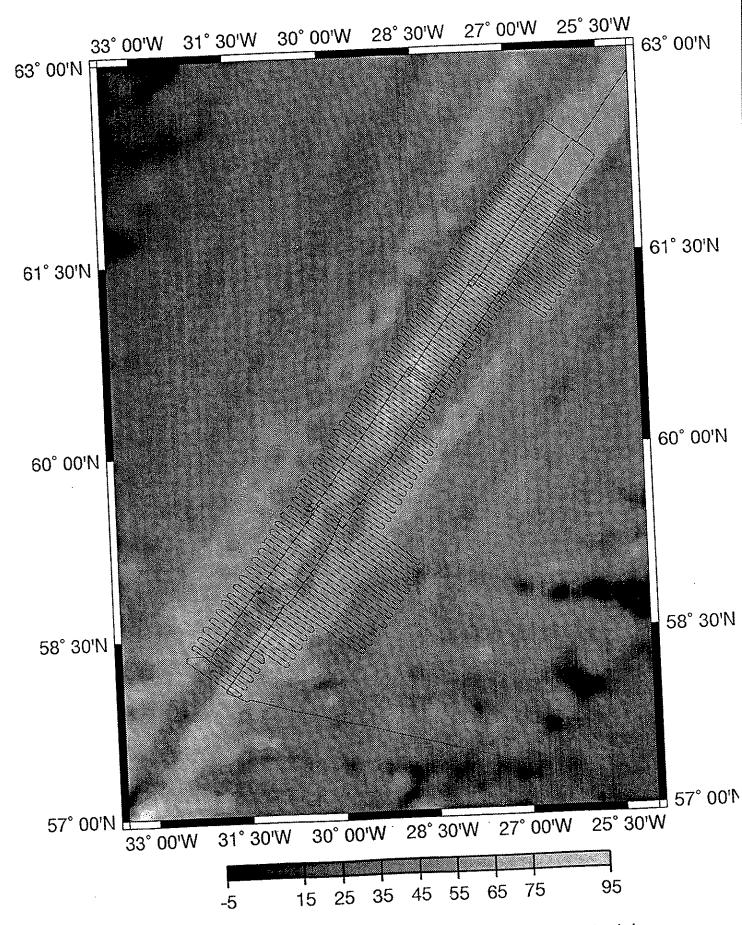

Figure 2 CD87 ship track superimposed over satellite gravity map. Scale bar is in mGal.

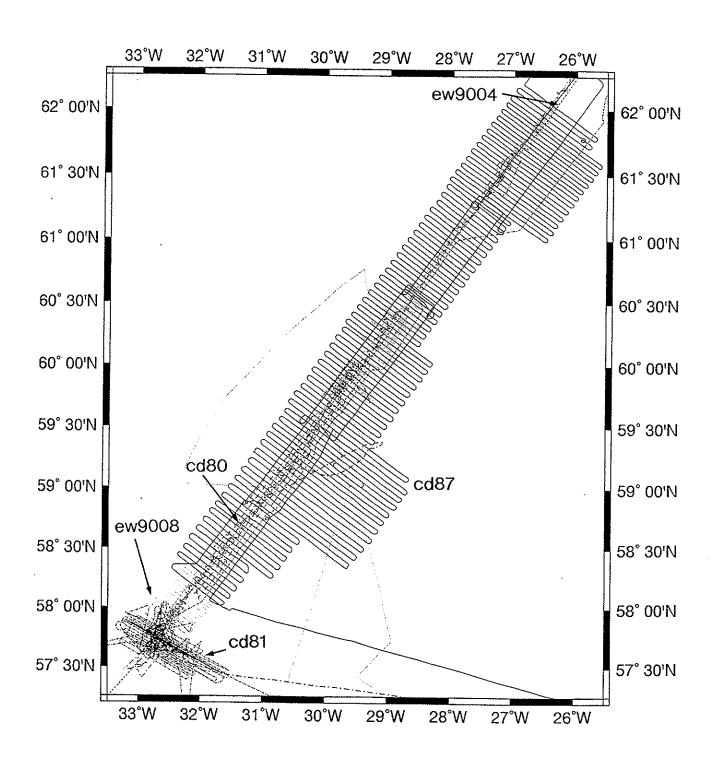

Figure 3 CD87, EW9004, EW9008, CD80 and CD81 ship tracks.

#### Tues June 21 (172)

Slowing to recover magnetometer and carry out velocity dip. 1125:

Start of velocity dip no. 2. 1210:

Completed velocity dip. Relaunch magnetometer, resume course 285°. 1322:

Start of Reykjanes Ridge survey, Area D, way-point 1 (see appendix A3 for waypoint 1413: listings). The survey begins at the northern limit of the 'EW9008 Area C', and the first

few lines were designed to fill in between existing coverage from that cruise.

Way point 4. A/c 036° for first of two tie-lines run parallel to ridge axis and outside 1851: existing multibeam coverage.

#### Wed June 22 (173)

Ended tielines and filling in. Started first of 7 lines oriented ridge-perpendicular and 1050:

spaced initially 4.5 km (way-point D12).

Increased line spacing to 5 km. This still gives almost 100% coverage. 1437:

#### Thur June 23 (174)

Way-point D26. Line length increased to 80 km to examine southern termination of 'V-1452: shaped ridge', for the next 9 lines.

Fri June 24 (175) Area D survey continued.

#### Sat June 25 (176)

End of Area D survey (waypoint D45). 0724:

Commenced tie-lines for Area E (waypoint E1) 0758:

Weather worsening towards evening.

Tie-lines complete; commencing main Area E survey with 130 km-long-lines (way-2036:

point E6).

#### Sun June 26 (177)

Full Gale by morning. Ship slowed to 5 knots; EM12 missing pings frequently. Air in sound velocity tank preventing sensible readings.

First plots of gridded bathymetry and magnetics produced for Area D. Weather abating. 1800:

2400: Back to full speed.

#### Mon June 27 (178)

Good weather. Survey E continuing.

#### Tues June 28 (179)

Good weather. Survey E continuing. Making speeds of almost 12 knots.

2009-2100: Fifty minutes of data lost from EM12 when active logging file accidentally deleted.

#### Wed June 29 (180)

Sea continuing very calm, with light swell.

Line spacing reduced from 5.0 km to 4.5 km after waypoint E29. 0949:

#### Thur June 30 (181)

Weather still calm. Clear skies, and continuous twilight tonight. Slight fog in morning.

EM12 stopped transmitting - communications error? Not immediately noticed by 0831:

watchkeeper.

EM12 restarted. 0938:

Looped round to fill gap on previous line caused by morning's transmission loss. 1451:

Back on course. 1700:

#### Fri July 1 (182)

Way point E47. Turned north for tie-lines of area F. 2157:

Way-point E48. Start of tie-lines. 2242:

#### Sat July 2 (183)

1352: Way-point F3. End of tie-lines.

1502: Way-point F4. Resuming last lines in area E.

#### Sun July 3 (184)

0443: End of Area E (way-point E53).

0506: Start of Area F, with lines shortened to 80 km (way-point F5).

#### Mon July 4 (185)

#### Tues July 5 (186)

Weather remains fair.

EM12 plots of areas C, D, and E have now been completed.

#### Wed July 6 (187)

Wind raised somewhat - force 6 by afternoon, but still making ca. 11 knots.

#### Thur July 7 (188)

Wind 30 knots, slowing us on some headings.

0015: Way-point F48. End of Area F.

0038: Start of area G, with lines shortened to 60 km. (way-point G1).

#### Fri July 8 (189)

Strong winds continue. Speed down to 4.5 knots at times.

#### Sat July 9 (190)

#### Sun July 10 (191)

Weather improving after three days of gales.

#### Mon July 11 (192)

Line-spacing kept at 4 km because of time lost in bad weather. This causes some (10-20%) swath underlap at axis, but much of this is filled by earlier cruises.

#### Tues July 12 (193)

Started tie-lines for Area H, at site of CD70 seismic experiment.

#### Wed July 13 (194)

Barometer fell sharply in small hours.

0133: Way-point H3. Commencing second tie-line, SW along ridge axis. Very slow progress into head seas.

1300: Speed dropped to 3.5 knots.

1328: Tie-lines complete.

1413: Resuming last lines of Area G.

1920: Way-point G78: end of survey area G.

1940: Way-point H5. Commence 93 km-long 125°/305° lines for 'Cambridge' survey in area of CD70 seismic experiments.

#### Thur July 14 (195)

Weather began to improve, but some courses still slow.

2300: Speed 6.2 knots.

#### Fri July 15 (196)

Weather gradually improved throughout day.

#### Sat July 16 (197)

Wind 20 knots (the lowest for days!) Back to speeds of 11.5 - 12 knots.

#### Sun July 17 (198)

Good weather. Survey H continues.

#### Mon July 18 (199)

1721: Polarisation failed on magnetometer.

1740: Magnetometer repaired and running again.

2240: EM12 stopped pinging during turn at 12 knots. Looped round while attempting to

restart equipment.

2338: EM12 working again.

#### Tues July 19 (200)

00:24 Rejoined survey line; short distance at start of line lost.

1124: WP 60: end of main Area H survey. Turned NW to reach continuation of northern

cross-axis leg of tie-line.

1327: A/c to SE, toward WP H3, in order to link with the northern arm of the Area H tie-line

and thus complete one further cross-axis traverse.

1457: End of cross-axis line. Slowing to recover magnetometer.

1521: Magnetometer recovered. A/c to NE for Reykjavik.

1600-1700: One hour's EM12 data lost because Mermaid failed to recommence logging after

change of 'line' (file) number.

1937: EM12 switched off at 63°N. Scientific watches ceased.

#### Wed July 20 (201)

0549: Commenced short gravity survey off-shore Reykjavik for University of Iceland Science

Institute (L. Kristiansson).

0819: Completed gravity survey.

1000: Docked in Reykjavik.

## 5. EQUIPMENT REPORTS

#### 5.1 EM12S-120

During the cruise, the Simrad EM12S-120 ran continuously for 720 hours. Overall, the system performed excellently, gathering data of a superb quality. 5 hours data were lost when the Mermaid logging system locked up (this was fortunately on the passage to the work area), 1 hour when Mermaid failed to respond after the main survey and a total of 4 hours lost with Bottom Detection Unit (BDU) lock ups. The BDU is responsible for determining the range to the seafloor of every beam. A full calibration was carried out at the beginning of the cruise. Four sound velocity profiles were taken and XBTs deployed most days (see appendices A4 and A5), weather permitting.

#### 5.2 LaCoste and Romberg Gravitymeter S40

The gravitymeter sensor and platform electronics were installed in the electricians store close to the pitch/roll centre of the ship and the logging and control electronics in the constant temperature laboratory alongside the Bell gravitymeter. Apart from a gyro change on day 168 and a "full hard disk crash" on day 199, the meter operated reliably throughout the cruise.

#### 5.3 Bell Gravitymeter BGM3 SN 203

A loaned unit from the National Research Laboratories, Washington D.C was initially installed in the Research Vessel Base at Barry and apart from some instrumental drift during temperature stabilisation, in port checks confirmed its serviceable operation. The meter was transferred to RRS Charles Darwin and installed in the constant temperature laboratory and, apart from an initial malfunction indication during platform erection due to an unseated card in the Platform control power supply, the meter appeared to be operating correctly. Once a suitable Gaussian filter had been written to smooth the raw count data coming from the Pulse Rate Converter (PRC), it became apparent that during periods of rough weather this output was exceeding the stated range of between 5 and 45 kHz, and when this occurred the filtered output became noisy with consequent spikes. The sensor sub assembly and PRC electronics were checked by introducing "TEST" and "CALIBRATE" signals into them and logging the output over a two hour period. This appeared to suggest that the sensor subsystem electronics were operating correctly and the fault was confined to the sensor itself or associated electronics. Communications from Bell Aerospace via NRL suggested that the time period of the Low Pass filter components within the Summing Amplifier was too small to prevent saturation of the Pulse rate converter under high acceleration conditions and such components, being within the sensor assembly, were not serviceable at sea.

#### 5.4 Varian Magnetometer V75

Worked well throughout the cruise apart from a failure in the polarisation supply circuitry (Day 199). The unit was replaced with a spare which worked satisfactorily for the remainder of the cruise. Both systems have a good signal to noise ratio, however they still suffer from radio transmission interference at some frequencies.

#### 5.5 Computer Systems

The RRS Charles Darwin is equipped with a third generation distributed data collection and processing system which is based on a three level architecture: level A samples and time-stamps data collected from the scientific instruments and navigation devices on board; level B logs and backs up the data; while level C performs the processing of the data. Minor hardware problems were fixed on board; however, most problems encountered were due to heavy loading of the network. Huge quantities of data were collected by the EM12S-120, which filled up disk space rapidly and was constantly being transferred across the network.

Regarding the multibeam processing, Neptune 2 processing, data logging (Mermaid) etc. were carried out on the shipboard computer system situated in the scientific plot on the Darwin. For MB-System processing, we brought a Sun Sparc 10 computer, with 2.5 Gbyte external disk drive, plus exabyte and optical drives, and networked it with the shipboard systems.

# 6. DATA PROCESSING

#### 6.1 EM12S-120

6.1.1 Data handling All EM12S-120 data are logged using the Mermaid system in the form of datagrams - e.g. depth, position, sidescan etc. - all held in one 'raw' file. We chose to log amplitude and phase data as well as the crucial depth, position, sound velocity etc. The depth datagrams are actually recorded as depths rather than travel times, since the travel time to depth conversion, using sound velocity profile data, is performed prior to logging. We created new logging files hourly and they still reached some 12 Mb in size. All in all, throughout 30 days of EM12S-120 operation, we collected approximately 10 Gbytes of data. 80% of these comprised the amplitude and phase datagrams (if one were to log just pure amplitude datagrams, the volume would be reduced to a third). Raw data were transferred from the Mermaid logging workstation to an additional computer, then downloaded to both the Neptune and Durham machines for processing.

There were too much data for it all to reside on the hard disks of either the shipboard or Durham computers, so regularly throughout the cruise backups had to be made. These were done principally on exabyte (RVS) and optical disk (Durham - until we ran out of disks! - then exabyte). It is important to note that the ping rate of the EM12S-120 (and therefore data rate) varies according to water depth. Pulse lengths also vary between deep and shallow modes (Simrad, 1992); the threshold point is a water depth of approximately 1500 m - a typical depth over the Reykjanes Ridge. We generally collected data at a higher rate as we progressed through shallower water towards Iceland.

Intermediate processing products, such as edited hourly files, plus final grids and ancillary data also had to be backed up and archived. Processing typically requires intermediate storage 2 to 3 times the volume of the raw data.

- The basic stages for any multibeam processing **6.1.2 Processing outline** procedure are to:
  - 1. Merge bathymetry with navigation
  - 2. Edit the bathymetry data
  - 3. Grid
  - 4. Display

6.1.3 MB-System bathymetry processing MB-System (written by Dave Caress and Dale Chayes of Lamonth Doherty Earth Observatory) is based on a modular concept, output can be either NetCDF or ASCII and it directly links with the widely used GMT package (Wessel & Smith, 1991). Refer to Caress & Chayes (1994), Owens (1994) and Blondel & Parson (1994) for further details.

An initial link is required between the Simrad raw datafiles and MB-System. Simrad provide a series of input/output libraries to deal with their data formats, however we read them directly. First each raw datafile must be split into its constituent datagram types (em12\_divide\_grams), then the depth and position data must be merged into one file (raw\_gram\_merge). These position data are the raw navigation logged direct from a GPS receiver, though smoothed navigation (output from the shipboard ABC computer system) can be substituted at a later stage within MB-System (mbmerge). MB will now read in the EM12S-120 data (recognised by its own specific id - Hydrosweep, Sea Beam etc. have their own ids). These initial procedures can simply be incorporated into a shell.

The next stage in multibeam processing is to edit the data. MB-System includes both automatic statistical (mbclean) and manual interactive (mbedit) editing. The statistical methods include rejection of slopes greater than a critical value, removal of a specified number of outermost beams etc. However, from viewing our data ping-by-ping, the artifacts are not necessarily predictable and would not be easily distinguished statistically (or by eye sometimes!), particularly since we were surveying over rugged mid-ocean ridge terrain. We found that interactive editing was essential. Some typical artifacts were:

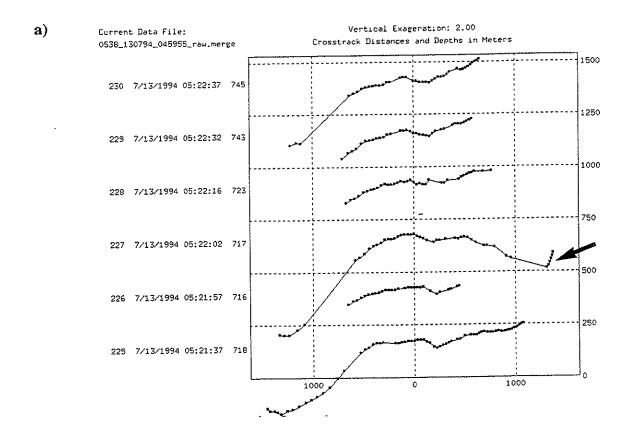

- · occasional 'curl-up' of outermost beams
- 'loses bottom' on steep slopes (across- and along-track)
- spurious depths from outermost (and very occasionally other) beams
- whole ping recorded as 'parabola' (bad weather attitude sensor problems)

Figure 4 presents some examples of these artifacts. We shall not attempt to explain the reasons for the artifacts here, though the reader could refer to de Moustier & Kleinrock (1986) for further details (they specifically deal with Sea Beam, but some of the problems are similar). We certainly recommend viewing the data in this manner to ensure artifacts are not interpreted as geological features and to realise the limitations of the system when imaging steep fault scarps, for example.

Generally the data were of <u>very</u> high quality. We were able to keep up editing with the data collection rate thanks to careful editing by watchkeepers (taking something like 6-8 man hours per day). On such a cruise though, other watchkeeping duties are limited.

After incorporation of smoothed navigation, the bathymetry data are ready to be gridded. The mbgrid routine limits the array sizes for gridding (somewhere around 300×300 nodes), so large areas must be divided into blocks, then pasted together after gridding (using GMT's grdpaste). Gridding is based on a Gaussian weighted scheme, which can be supplemented by interpolation (thin plate spline) over the data gaps.

Plots were generated using MB and the GMT freeware package (Wessel & Smith, 1991) and hardcopies made on any postscript printer. We managed to produce a large scale, colour-fill plot of all the data onboard (even though it involved sellotaping together almost 200 A4 sheets!). Figure 5 presents a scaled down version of the final grid.

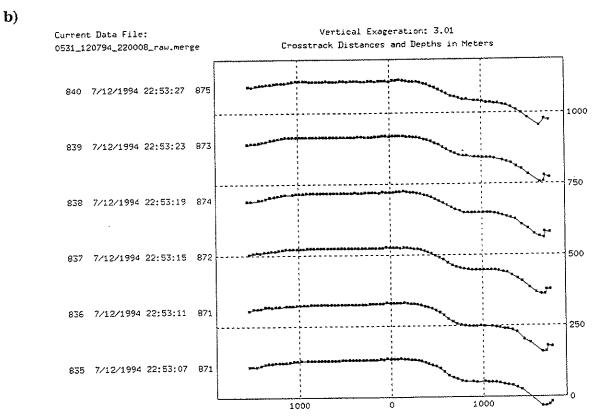

Figure 4 Examples of some typical EM12S-120 artifacts identified during editing: a) 'curl-up' of outermost beams; b) spurious depths from outermost beams.

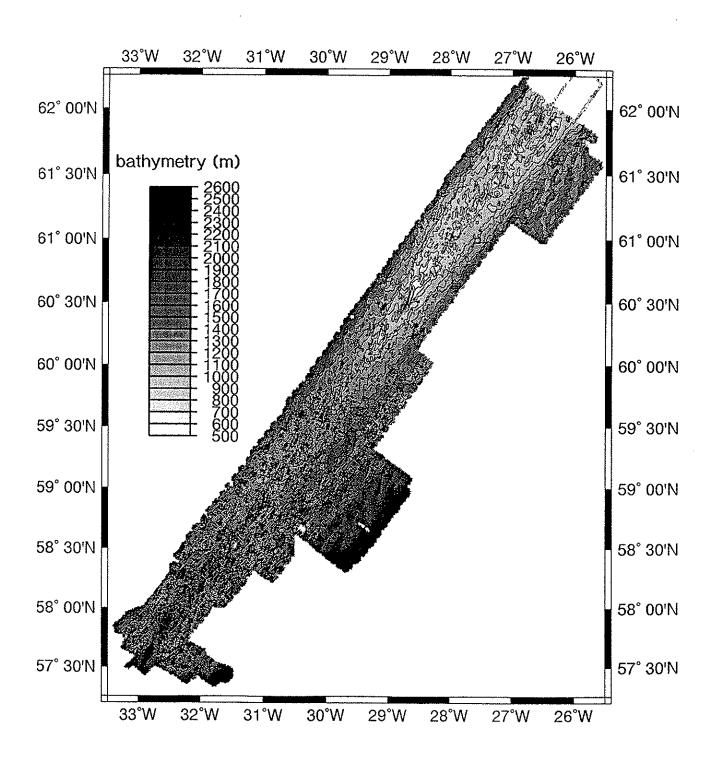

Figure 5 CD87 bathymetry data. Contour and grey scale at 100 m intervals.

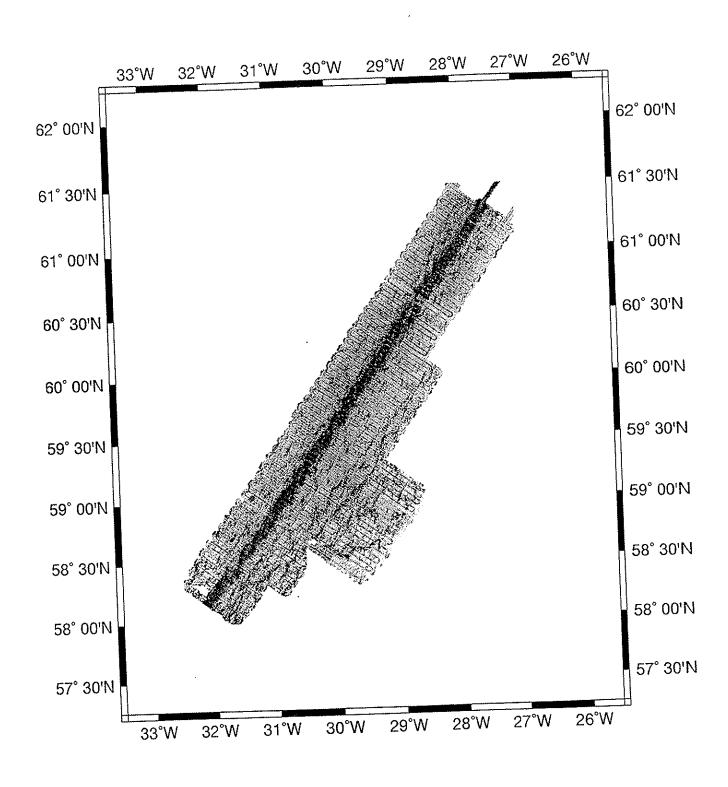

Figure 6 CD87 sonar imagery data. Black is equivalent to 0 dB, white to -64 dB.

- **6.1.4 Neptune 2 bathymetry processing** Neptune 2 is the standard bathymetric, data processing and cleaning package provided by Simrad A/S for use with the EM series of multibeam echo sounders. The Neptune 2 system enables editing, correcting, cleaning, thinning, terrain modelling and plotting, given data transferred from the Mermaid logging system and other sources. The processing of data is performed in four dedicated modules, which are presented using X11/Motif:
  - Position Processing including spike removal, smoothing and merging positions from different sensors.
  - Depth Processing corrects for systematic errors, such as caused by an incorrect sound velocity profile (recalculation, editing), offset errors (e.g. time, roll, pitch, gyro, heave etc.) and also estimates depth errors.
  - BinStat Data Cleaning statistical calculations are performed on depth data, defined within geographical blocks. All depths from any line in a survey that fall into a block are read, gridded and analysed with the statistical information of the cells being presented as colour coded maps. A range of correlation plots (one depth aspect versus another) exist which help the user to spot problem areas, and the data cleaning tools of BinStat can be used to clean the data. The XYZ point data can be output in ASCII and binary form.
  - Terrain Modelling and Plotting an application of IRAP (Interactive Reservoir Analysis Package) written and supported by Geomatic A/S. Typical functions include the input/output of different file formats, fast and accurate gridding, terrain modelling, geodetic transformations, contouring, cross sections, 3D plots etc.

The Neptune 2 processing routine during CD87 was to establish a set of data blocks within pre-defined work areas, clean the data in each of the blocks using the BinStat module and then grid using IRAP. The Position Processing module was not required because the smoothed navigation was transferred from the shipboard ABC system and the Depth Processing Module was not used because the calibration offsets were set at the data source.

6.1.5 Sonar imagery processing The amplitude and phase datagrams were logged but not consulted any further onboard ship. However in the EM12S-120 depth datagrams, mean beam amplitudes are recorded alongside depths. Using MB-System, we were able to construct rudimentary 'sidescan' mosaics for all the cruise data, which proved very useful in defining zones of recent volcanism (figure 6 displays the amplitude data processed on board). Keeton and Mitchell (1994) describe the interpretation of multibeam sonar images. One must note the data volume and processing capacity that would be required to process the 'full resolution' imagery - the mean beam amplitudes are certainly sufficient for starters.

**6.1.6 Summary** Both Neptune 2 and MB-System provide excellent means for processing EM12S-120 multibeam bathymetry data. The packages are quite different in concept, design and interface style. Neptune 2 is permanently installed and supported on the Darwin, however MB is freely available to universities/institutes and

well-documented source code is available. Both systems operated successfully, and could produce the gridded product and maps by the end of the cruise. We only switched the EM12S-120 off 24 hours before arriving in port, and the last (sizeable) block of data was processed and printed out in time. Additionally, the volume of data collected and size of processing products emphasises the importance of careful backing up and quite what is involved (capacity-wise) in terms of archiving facilities.

#### 6.2 Gravity

Crossover adjustment was performed on the LaCoste and Romberg data by an iterative matrix method and involved applying dc offsets to individual straight segments of data to minimise the overall rms crossover error. Before crossover adjustment, the rms crossover error was 6.8 mGal (figure 7a), which improved to 3.0 mGal after the adjustment (figure 7b).

It became apparent after examining cross-over errors and comparing profiles of the LaCoste and Romberg with the Bell BGM3 data, that the two gravitymeters were inconsistent between east to west and west to east survey lines. While on reciprocal courses, significant cross coupling errors (as large as 15 to 20 mGal) were evident, particularly during periods of moderately rough to rough weather. It was therefore decided to back off 6 days of gravitymeter data onto floppy disk from the gravitymeter hard disk during a sound velocity station, in order to do a cross correlation of cross coupling errors with gravity using a proprietary P.C. based program supplied by LaCoste and Romberg. The program calculates the optimum amounts of recorded cross coupling monitors to be added to gravity in order to eliminate any correlation between the curvatures (first derivative) of the monitors and gravity. The process was undertaken twice; once by utilising the recorded cross coupling and once by omitting it in order to verify the fractions contained within the cross coupling parameter menu in the gravitymeter. Once corrected fractions had been calculated, these were used to recompute the recorded data and to compare the recomputed profiles against the Bell gravitymeter. A significant improvement of the data was noticed reducing the differences between the two profiles from 10 to 2 or 3 milligals in the worst cases observed, although some residual course dependent error still remained.

After the cruise, the entire dataset was re-processed to remove the cross coupling effects. Before crossover adjustment, the crossover errors now improved to 3.6 mGal (figure 7c), and after adjustment, these were reduced to a satisfactory 0.8 mGal (figure 7d). Tie-ins were made to gravity base-stations in Barry and Reykjavik, yielding a drift of 0.09 mGal per day. The free air gravity data are displayed in figure 8. A preliminary mantle Bouguer anomaly was also produced on board.

#### 6.3 Magnetics

Magnetic anomaly data were reduced to IGRF, but diurnal and storm variations were not removed (figure 9). The anomalies were inverted to crustal magnetisations on board, using the method of Parker and Huestis (1974).

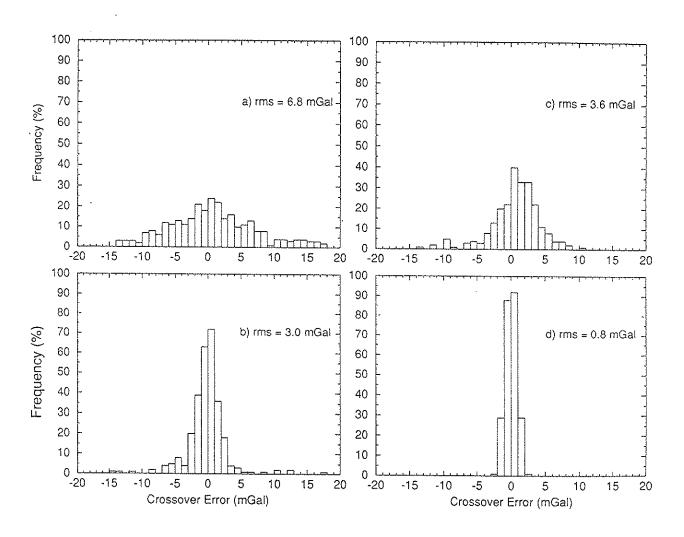

Figure 7 Crossover adjustment statistics for CD87: a) crossover errors before adjustment; b) crossover errors after adjustment; c) crossover errors before adjustment and after cross coupling correction; and d) crossover errors after adjustment and cross coupling correction.

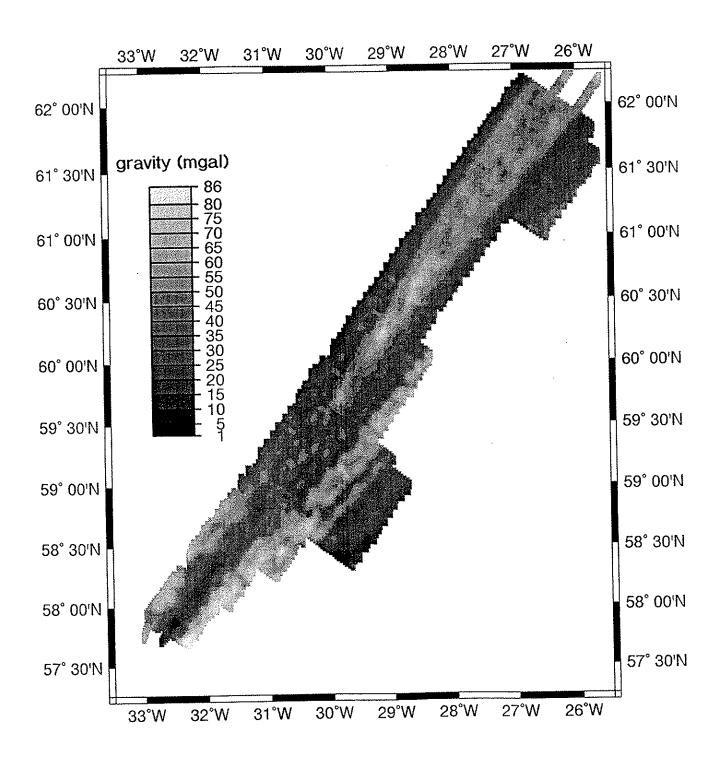

Figure 8 CD87 free air gravity.

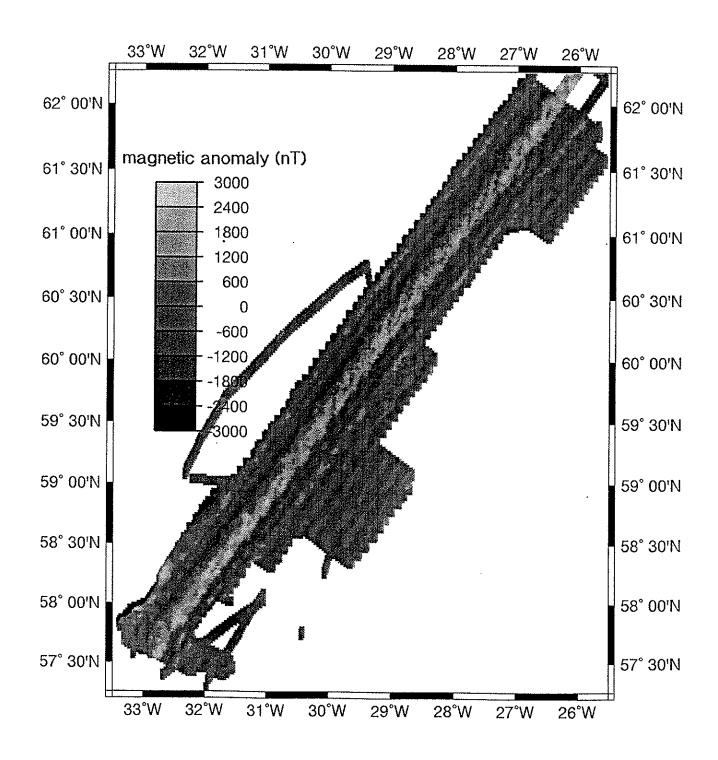

Figure 9 CD87 magnetic anomaly data.

### 7. PRELIMINARY CONCLUSIONS

Based on our initial shipboard examination of the data, some very preliminary conclusions are as follows:

We find that the Reykjanes Ridge axis and flanking isochrons are extremely linear and suffer no significant offsets for at least 580 km north of 57°55'N. Over the whole of this distance the ridge axis is 36° oblique to the spreading direction. There is an ubiquitous pattern of en echelon axial volcanic ridges (AVRs) sub-normal to the spreading direction along the whole length of Ridge surveyed.

Relict Axial Volcanic Ridges are most frequently seen off-axis where there is least axial faulting, tending to confirm that elsewhere they are rapidly eroded by faulting, as suggested previously by Parson et al. (1993). The axis is flanked by normal faults that are sub-parallel to the Ridge axis, the innermost of which occur slightly closer to the axis as one goes towards Iceland. Although the amplitudes of AVRs and faults varies along and across the ridge, the basic plan view pattern does not. We believe this pattern represents the basic response of the lithosphere to oblique spreading.

Generally, the amplitude of faulting decreases as Iceland is approached. In particular, there is negligible large-scale faulting near the axis north of the 'median valley/axial high' transition, which occurs near 58°50'N. However, towards the northern end of the Ridge (61°15' to 61°55'N) some near-axis small-scale faulting returns. Thus the morphology does not change in a simple monotonic manner as the Iceland hotspot is approached. The central part of the area studied (about 59° 40'N to 61° 15'N) appears to represent one end member, with large numbers of central volcanoes, no large-amplitude near-axis faulting, and no median valley. It also has the most linear and symmetric magnetic isochrons. To the north and south, the amplitude of faulting increases, the density of volcanoes decreases, and isochrons show a greater tendency for asymmetric spreading, nonlinearity or small offsets. Most of these variations probably reflect changes in mantle temperature, and the culmination of them in the central region suggests the existence there of a local temperature high, possibly reflecting a transient pulse of high plume output and perhaps the latest (previously unrecognised) V-shaped ridge.

There is an axial zone of high backscatter, some 10-15 km wide, marking the zone of recent volcanic activity. The width of this zone remains approximately constant (apart from small local disturbances) along the length of the Ridge, and in particular does not depend on the existence of a median valley to delimit it.

Even where there is no sign of a median valley near the axis, flanking lines of high fault-blocks persist off-axis along the ridge length. Their heights vary along the ridge (suggesting a segmentation pattern) but they are not laterally offset. Relative highs and lows in these 'crestal mountains' tend to alternate from side to side across the axis, but, at least in the south, are slightly higher on the SE side.

The mantle Bouguer anomaly is very smooth, exhibiting little mid- to short-wavelength variation above a few mGal. Along-axis variations in the mantle Bouguer anomaly are of very low amplitude compared with other parts of the Mid-Atlantic Ridge.

The main 'V-shaped ridge' (which converges on the axis near 58°30'N) is morphologically discontinuous, being composed of lines of closely-spaced but distinct tectonic blocks. The innermost of these ridges comprises three closely-spaced, parallel bands of such elevated blocks. The ridge displays an internal tectonic fabric which is similar to that on the surrounding seafloor, but of higher amplitude (i.e. bigger fault scarps). There is no evidence of off-axis volcanic activity or abnormal numbers of volcanic seamounts on the V-shaped ridge. The gravity signal over the V-shaped ridge is of much greater amplitude than expected from the observed bathymetry, which suggests compensation via regional rather than pointwise local isostacy.

Magnetic anomalies are very linear, departing from great circles parallel to the axis by less than 15 km, mostly in a slow regional variation. Local kinks in the Brunhes of up to 3 km in along-axis distances of 20-30 km occur at 59°12'N, 60°23'N and 61°28'N; none of them are associated with significant morphological discontinuities. Similar kinks in older stripes are not aligned. A larger bend to near NS anomalies at 57°50'N affects most isochrons and is associated with offsets and missing anomalies, confirming this as the first significant ridge-axis discontinuity south of Iceland and suggesting a history of ridge jumping or propagation here.

Spreading has mostly been constant at  $10.6 \pm 0.3$  km/My over the past 10 My, and has been symmetric to within 5% or better over at least the past 2.8 My. Exceptions are south of 57°50'N (see above), and north of 61°28'N where spreading appears to have been faster to the east since 2.8 My.

Magnetisation amplitude varies along all isochrons by factors of about 2 over distances of 15 to 35 km, much greater than the AVR spacing. These variations are weakly correlated with morphology: some highs occur near the southern ends of AVRs suggesting a possible link with AVR-scale magma propagation; some lows occur near the centres of AVRs suggesting possible influence from hydrothermalism or shallow isotherms. The variations are not aligned or correlated with the 'V-shaped' diachronous ridges or with distance from Iceland. A superimposed short- wavelength pattern correlates strongly with the en-echelon AVRs. We are testing whether it is real or a residual terrain effect incompletely corrected by the inversion. If real, it may reflect variations in mineral composition and/or crustal temperature at the AVR scale.

### **ACKNOWLEDGEMENTS**

We wish to thank the master, officers and crew of the RRS Charles Darwin and the RVS technicians for all their help in ensuring a highly successful cruise. We also thank the Natural Environment Research Council (BRIDGE programme) for funding the work. Dave Caress and Dale Chayes of Lamont Doherty Earth Observatory are

acknowledged for the provision of the MB-System multibeam processing software. Bruce Appelgate, Sandy Shor (University of Hawaii), Christine Peirce (University of Durham), Martin Sinha (University of Cambridge), Lindsay Parson and Bramley Murton (IOSDL) are all thanked for providing data from their cruises.

<sup>&</sup>lt;sup>1</sup> A salinity of 35 ppt is assumed.

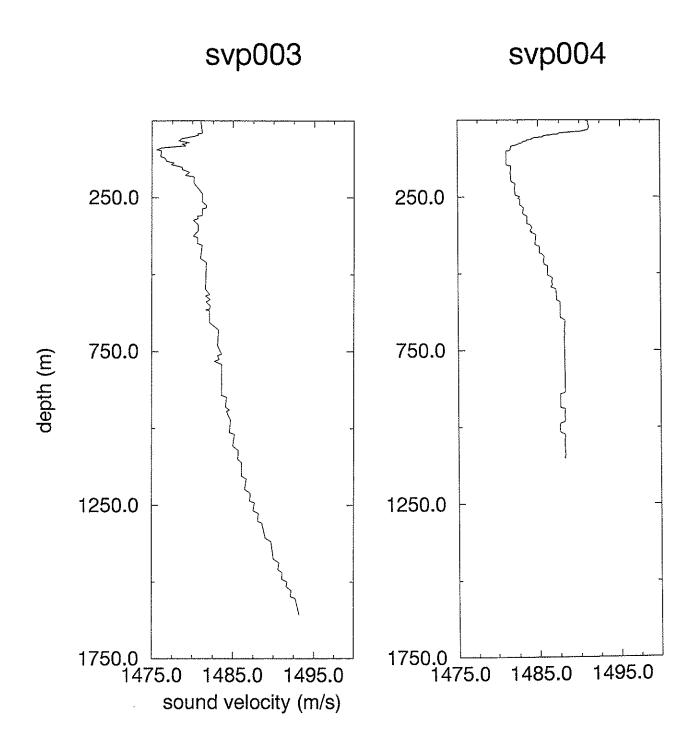

A5. Sound velocity profile

These are the sound velocity profiles used to convert travel times to depths for the EM12S-120 during cruise CD87. The profiles were read into the EM12 system immediately after each dip was taken (see appendix A4).
